FEBRUARY 2005

ABSTRACT

A mark-recapture program was conducted on the Porcupine River near the community of Old Crow, YT during the fall of 2004. The main purpose of this project was to attempt to quantify the run size (in-season) of the fall run of chum salmon (*Oncorhynchus keta*). A tagging fishery was located 24 km downstream of Old Crow to capture and mark chum salmon on their upstream migration. A test fishery was operated 2 km downstream from Old Crow in an attempt to recapture tagged chum salmon. Both fisheries were conducted using constantly monitored gill nets, and involved the collection of various pieces of biological information. In addition, an enumeration weir located on the Fishing Branch River recorded tag numbers passing through the weir. Through the use of data collected in the mark-recapture program and at the Fishing Branch weir, an estimation of the run strength was calculated. A total of 1,276 chum were tagged and 1,187 chum were caught in the test fishery, including 35 tag recoveries.

1.0 INTRODUCTION

A lack of stock assessment information has been identified as a barrier to the successful local management of Porcupine River chum salmon (*Oncorhynchus keta*) stocks. In past years, the only estimate of run-size was an escapement count from an enumeration weir on the Fishing Branch River, a major spawning destination for Porcupine River chum. Therefore, there has been no “in-season” estimate available before or during the Old Crow subsistence fishery. With declining stocks in recent years, such an estimate has become necessary to enable effective local management of the Old Crow fishery. Local managers have identified establishing an in-season program to assess run strength as chum stocks reach Old Crow as a priority.

In 2003, a chum salmon mark-recapture effort was undertaken on the Porcupine River as an attempt to assess the strength of the run of chum salmon passing by Old Crow. Moderate numbers of chum salmon were tagged during this effort; however the numbers of fish tagged and recaptured were insufficient to accurately predict the run strength “in-season”(Anderton 2003).

This project builds on the 2003 project results to provide an accurate “in-season” estimate of Porcupine River chum stocks. The objectives of this project included:

- Inspire and build community capacity and stewardship for the conservation, restoration, and enhancement of salmon stocks and their habitat in the Porcupine River sub-basin through the development of the human capacity in the community of Old Crow.
- Restore chum salmon stocks by directly increasing spawning escapement through providing effective “in-season” management.
- Provide information on the proportion of Porcupine River chum stocks that spawn in the Fishing Branch River through the use of tag recoveries at the Fishing Branch Weir.
- Set the stage to ensure the long-term conservation of the chum salmon resource and its' habitat in the Porcupine River sub-basin by giving community members the required knowledge and experience.

1.1 Study Area

The Porcupine River is one of the largest tributaries in the Yukon River watershed (Figure 1). It extends from its mouth at Fort Yukon, Alaska, across the Canada/U.S. border where it drains a large portion of the north Yukon and most of the Vuntut Gwitchin First Nation’s Traditional Territory. The Porcupine has a number of large tributaries in Canada, including three significant rivers that form its headwaters: the Whitestone, Miner, and Fishing Branch Rivers. The only significant Canadian settlement within the Porcupine River watershed is the village of Old Crow, located approximately 80 kilometres east of the Canada/U.S. border at the mouth of the Crow River. Old Crow has a population of approximately 300, mainly Vuntut Gwitchin First Nation members.

Three species of salmon migrate up the Porcupine River. These include chinook (*Oncorhynchus tshawytscha*) which pass Old Crow mainly during the month of July, chum (*Oncorhynchus keta*) which pass Old Crow mainly in September, and coho (*Oncorhynchus kisutch*) which pass Old Crow between early October and late January. There have also been reports of summer chum and fall chinook in the vicinity of Old Crow.

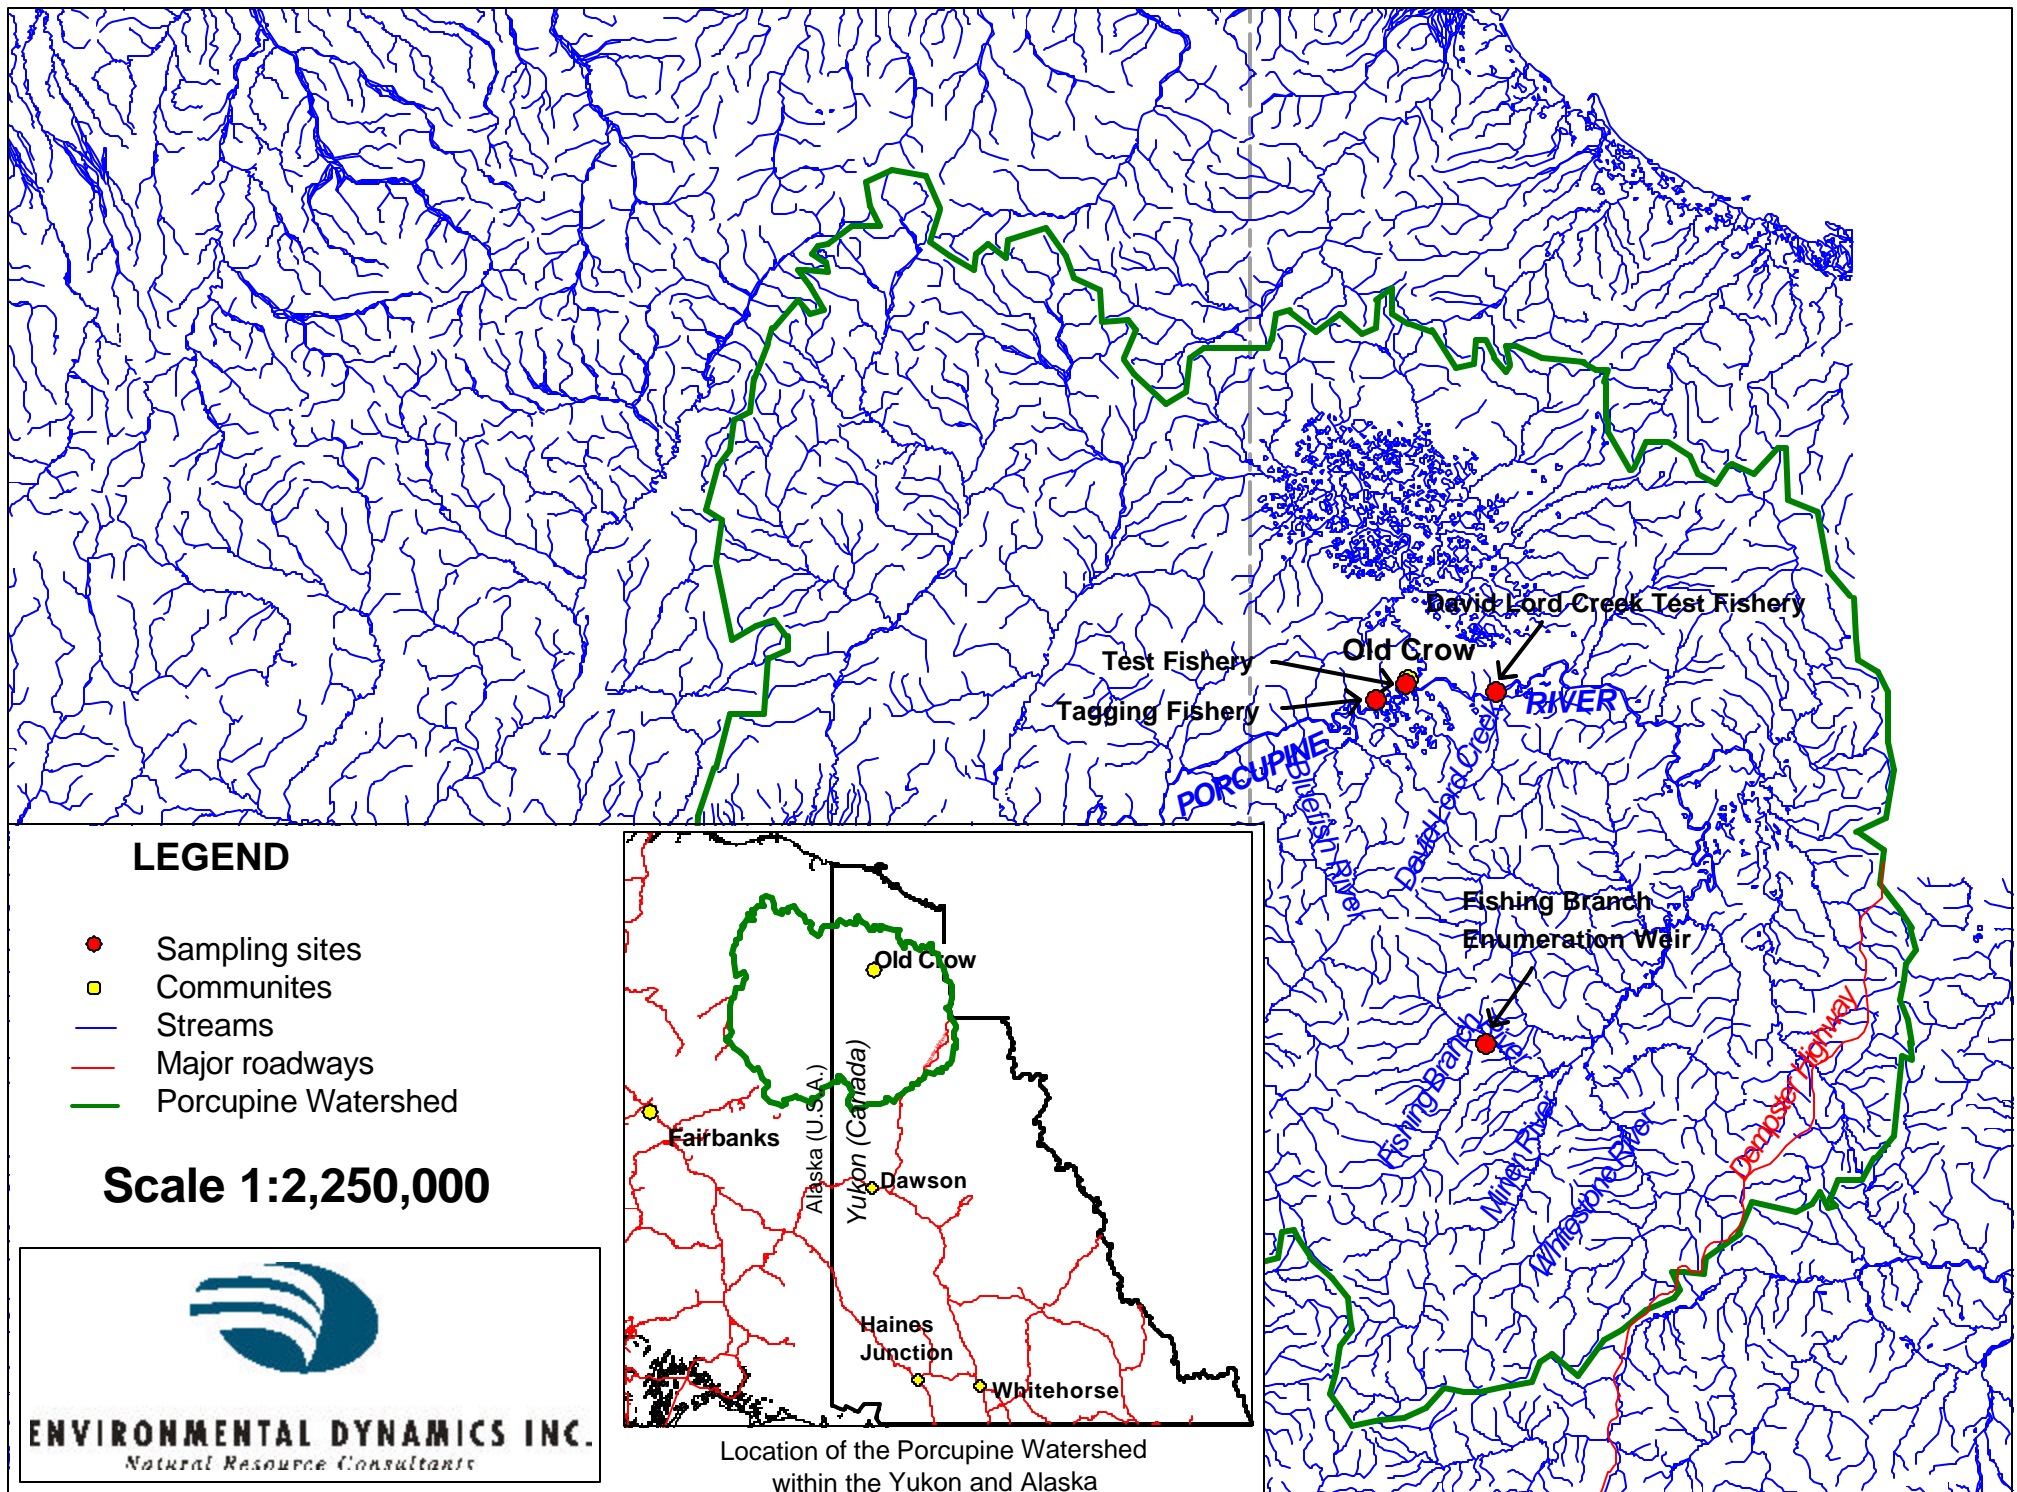

Figure 1. Map of study area.

The site used for the tagging component of the project remained fixed throughout its duration and was located approximately 24 kilometres downstream of Old Crow (Figure 1). The site used for the recapture component was initially located approximately 12 kilometres upstream from Old Crow. This site was utilized only during the first one and a half days of attempted recapture. During the remainder of the project, the test fishery was located approximately 2 kilometres downstream from Old Crow.

Photo 1. The study site showing the net set location used in the test fishery.

2.0 METHODS

Two crews of two people¹ carried out both the tagging and test fishery components for eight to ten hours per day for six days per week. The start date and days off were planned to allow a one-day delay between tagging and the test fishery. Tagging was initiated on August 25, and ceased on September 27, 2004 and the test fishery began on August 29, and ceased on September 28, 2004. Due to logistical problems there were two consecutive days when tagging did not occur (Sept 22 & Sept 23, 2004). In order to salvage data collection in the test fishery, netting was carried out approximately 38 km upstream from Old Crow at the mouth of David Lord Creek on September 23. The fish captured at this location were not included in the run estimations, as it was not possible to accurately distinguish between spawning and migrating fish at this location (see Section 4.2 for further information).

Gill nets used were one hundred feet in length, six feet deep and composed of four and a half inch mesh. Nets were set at a fixed location and closely monitored at all times. When fish were captured, they were immediately removed from the net (see photo 2). Fork length and sex was recorded in addition to any other significant observations (see photo 3 and 4). At the tagging site, orange spaghetti tags were applied

¹ 3 members of the Vuntut Gwitchin First Nation and 1 biologist from EDI Environmental Dynamics Inc.

directly behind the dorsal fin of each chum salmon (tag sequence: T000319 to T001497 and C00501 to C00635). In addition to being fitted with a spaghetti tag, the chum were given an adipose fin punch to serve as a secondary marking in the case of tag loss. Fish caught in the test fishery were not tagged, however they were marked with an adipose fin or tail punch.

Photo 2. Crewmembers checking the gill net in the tagging fishery.

Photo 3. A chum salmon being measured prior to release back into the river.

Photo 4. A chum salmon being removed from the gill net prior to measurement and release.

All sampling for this project was carried out under fish collection license CL04-44, issued by the Department of Fisheries and Oceans (DFO) on August 23, 2004.

As tagged chum salmon passed through the Fishing Branch weir, tags were recovered and associated information was recorded². This tag recovery data was used to estimate travel times, and is presented in Appendix 8.2.

All data collected in this study was summarized, analyzed, and has been detailed in section 3.0. Mark recapture estimations were made using the Chapman's (1954) modification of the Lincoln-Peterson mark-recapture model, as per the following formula:

$$N_C (\# \text{ of fish}) = \frac{(N_1 + 1)(N_2 + 1)}{(M_2 + 1)} - 1$$

The 95% confidence interval was also derived using the following formula:

$$\text{variance } (N_C) = \frac{(N_1 + 1)(N_2 + 1)(N_1 - M_2)(N_2 - M_2)}{(M_2 + 1)^2(M_2 + 2)}$$

$$95\% \text{ CI} = N_C \pm 1.965 \sqrt{(\text{variance } (N_C))}$$

All variables are detailed in Table 4. In the confidence interval formula, 1.965 is a constant value referred to as a Z-value when using a 95% confidence interval with an infinite number of degrees of freedom in a two-tailed random distribution (Chapman, 1954).

² This component was conducted by Fisheries & Oceans Canada

When using the Lincoln-Peterson mark-recapture model, there are three main assumptions (Lancia et. al 1996):

- All individuals have the same likelihood of being captured.
- Tags are not lost or gained between mark and recapture events.
- The population is closed to immigration and emigration.

The first assumption is valid because gillnets were placed in fixed locations on the Porcupine River where all fish had an equal likelihood of being captured. The validity of this assumption is further substantiated by the fact that differences in the proportion of males caught in both the tagging and test fishery were small. The second assumption is valid, first because no other tagging activity was taking place on the Porcupine River, and also, as tagged fish also received a secondary mark to ensure that those which may have lost their tags were not counted in the test fishery. The third assumption is valid for the test fishery (near Old Crow) because there were no chum salmon entering the Porcupine River between the tagging and test fishery location and there are no known spawning locations between the tagging site and the test fishery. Although it is possible that there were a very low number of mortalities resulting from the stress of being tagged this effect would be minimal. This effect would be minimal as the number of mortalities associated with handling was likely very low. For the Fishing Branch weir, there is emigration in the form of fish spawning in the mainstem and tributary streams. For the purposes of this study it was assumed that emigration occurred at the same rate for tagged and non-tagged fish. This assumption should be true given that the second assumption appears valid.

3.0 RESULTS

The results obtained during the tagging and test fisheries are outlined in the sections below. The run estimate for each week during the program is also included in addition to tag recoveries at the Fishing Branch enumeration weir.

3.1 Mark/Recapture Results

Tables 1 and 2, respectively, summarize the results of the tagging and test fishery program. See Appendices 8.3 and 8.4, respectively, for detailed information of all fish captured. Variation in the number of days per week of mark/recapture effort was due to both logistical problems and weather conditions of the river such as periodic severe winds and heavy ice flows near the end of September. Table 3 details the test fishery results from the mouth of David Lord Creek on September 23, 2004, which was also observed to be a spawning location (see Section 4.5). Table 4 presents the run estimations for each week of mark/recapture effort, as well as for the entire sampling period. Figure 2 illustrates the proportion of males captured in both the tagging and test fisheries.

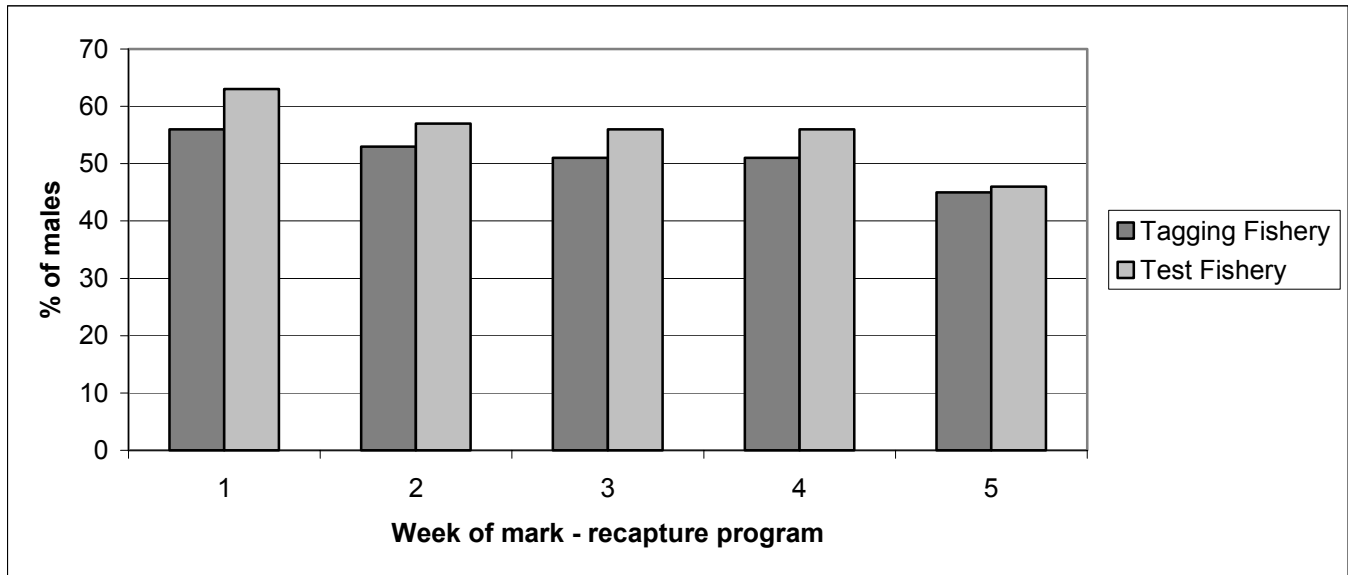

Figure 2. Proportion of males captured in the tagging and test fisheries over the duration of the mark-recapture program.

3.2 Tag Recovery at the Fishing Branch Weir

Of the 1,276 chum salmon tagged during the mark-recapture program, 673 tags were recovered at the Fishing Branch weir. The tag numbers recovered ranged from T000321 (the third tag applied) to T001492, and, 136 tags were applied after this tag number (T001492). Virtually all the tags that passed through the weir were recovered this year (as opposed to 2003 when they the majority were observed but not recovered). The Fishing Branch weir was pulled on October 10th, however significant numbers of chum were still arriving at that time. Considering these factors, the 136 chum tagged after the last tag number recovered must be subtracted from the total number tagged to estimate the proportion of the run that passed through the Fishing Branch weir. In doing so, the proportion of the tags that passed through the weir was 59% of the number of chum salmon tagged in the mark-recapture program. See Appendices 1 and 2 for further information regarding individual tag recovery at the Fishing Branch weir.

³ Calculation for total run estimate done using the total numbers of the mark-recapture program due to overlap of tag recoveries between weeks.

3.3 Travel Time of Tagged Chum

All chum salmon were captured and tagged at a location approximately 24 km downstream of Old Crow. Therefore, the 35 tagged fish caught in the test fishery at the location approximately 2 km downstream of Old Crow traveled approximately 22 km. The average travel rate for chum salmon between the tagging and test fisheries was 26.4 km/day, with a range of 6.3 km/day to 37.2 km/day. The 673 tags recovered at the Fishing Branch weir traveled a distance of approximately 376 km. The average travel time between the tagging site and the Fishing Branch weir was 25.2 km/day with a range of 15.0 km/day to 34.2 km/day. See Appendices 1 and 2 for detailed information regarding the travel time of each tagged chum salmon recaptured in the test fishery and at the Fishing Branch enumeration weir.

4.0 DISCUSSION

The mark-recapture program was able to provide an estimate of the size of the fall chum salmon return to the Porcupine River during the fall of 2004. However, there was a large margin of error surrounding this estimation, which can be mainly attributed to a low number of tags recaptured in the test fishery. Further estimates made using tag recovery data from the Fishing Branch chum enumeration weir provided an additional reference with which to compare the mark-recapture results. A much lower proportion of tagged chum salmon were recovered at the Fishing Branch enumeration weir during this year than in 2003 (59% compared to 88%; Anderton 2003). The discovery of spawning chum salmon at David Lord Creek supports the claim that during some years there may be many other spawning locations within the Porcupine watershed in addition to the Fishing Branch River.

4.1 Mark – Recapture Program Effectiveness

A significant number of chum salmon were caught in both the tagging effort (1276) and the test fishery (1187). Based upon the results of both, population estimates were made (See Table 4). In order to demonstrate the relevance of these estimates, a 95% confidence interval was used.⁴ The total population estimate was 42,140, with a 95% confidence interval of +/-13,215 (or between 28,925 and 55,355).⁵ The large confidence interval (or lack of accuracy) is further exaggerated in the weekly estimations (see Table 4), where it is always over half of the population estimate (in some cases much greater).

During the second and third weeks of the mark-recapture program, the run estimates calculated through the use of tag recoveries were very large due to the relatively low number of tags recovered in the test fishery. The number of tags recovered was much higher during periods in which there were fewer salmon being caught in the river. When operating a mark-recapture survey it is expected to recover fewer tags when the overall population size is larger. However, large numbers of fish were also being tagged during this time period and it is expected that a larger number of tags would have been recovered in the test fishery. Reasons for this lack of tag recovery remain uncertain.

⁴ This confidence interval demonstrates that with the sampling data obtained, the population estimates are accurate within the given interval 95 times out of 100.

⁵ Therefore this means that if the same mark-recapture program was run 100 times in 2004, the results would be within the confidence interval of 28,925 to 55,355 at least 95 times.

During the final week of the mark-recapture program, relatively low numbers of fish were captured in the test fishery, mainly due to adverse weather conditions. Very high winds combined with ice flows in the Porcupine River severely hampered the effectiveness of the test fishery during this time period. The complete data set for all sampling conducted under this project is presented in Appendices 3 and 4.

The total number of chum counted through the Fishing Branch weir was 19,664. It should be noted that a subsequent Fishing Branch estimate of 20,274 was released by DFO, however this figure is an estimate and is therefore not linked to known tag recoveries. Therefore the count of 19,664 chum has been used in all related calculations. As noted in Section 3.2, 59% of the applicable tags passed through the weir. Therefore, it can be assumed that this represents roughly the percentage of the chum run that actually migrated to spawn upstream of the weir in the Fishing Branch River. Therefore, it is evident that the enumeration weir did not account for a significant portion of the run.

Given the availability of the Fishing Branch tag recovery data, it is valuable to generate two additional population estimates as reference points for comparison with the mark-recapture program results. These reference points provide indications regarding the relevance and accuracy of the mark-recapture estimate.

Using both the data gathered in the mark-recapture program and that collected at the Fishing Branch weir, two additional run estimations can be formulated using the mark-recapture formula (Figure 3). While these estimates do provide a valuable indication of total run strength, it should be noted that all estimates do not represent the entire scope of the run. That is, the entire duration of the run was not sampled, both in the mark-recapture program, and at the Fishing Branch weir. The mark-recapture program began on August 25th after the beginning of the run, and finished on September 28th while chum were still migrating. The weir ceased operation on October 10th, while chum were still migrating. However, with analysis of run dynamics in past and current years (see Figure 4), it is clear the estimates are representative of the vast majority of the run.

It is important to note that while tag recovery occurred at the Fishing Branch weir, the entire Porcupine chum population (for all spawning destinations upstream of the tagging location) was sampled in the tagging effort. However, the first of the Lincoln-Peterson assumptions detailed in Section 2.0 may come into question in terms of the estimates generated using the Fishing Branch tag recovery data. That is, a significant amount of tagged chum salmon essentially exited the system to spawn in other tributaries or in the Porcupine mainstem itself. However, it has been assumed that an equal proportion of tagged to untagged chum exited the system as with those who migrated through the Fishing Branch weir. Therefore, the first of the Lincoln-Peterson assumptions has been considered valid for the two estimates generated from the Fishing Branch weir tag recovery data.

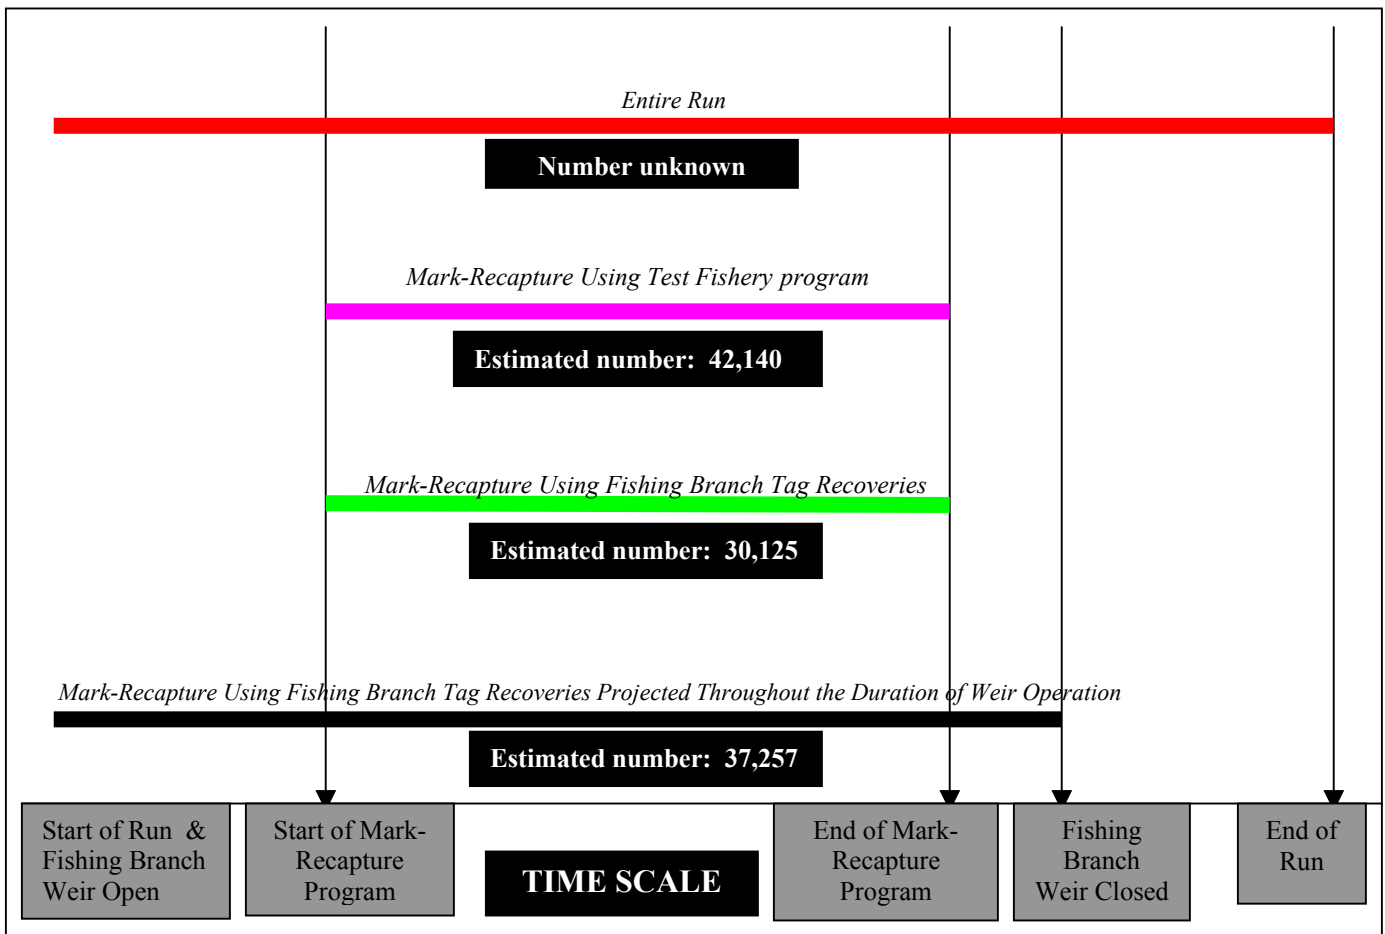

Figure 3. Relationship of three different methods used to estimate the run size of Porcupine River chum. The time scale has been adjusted based on relative timing considering migration timing.

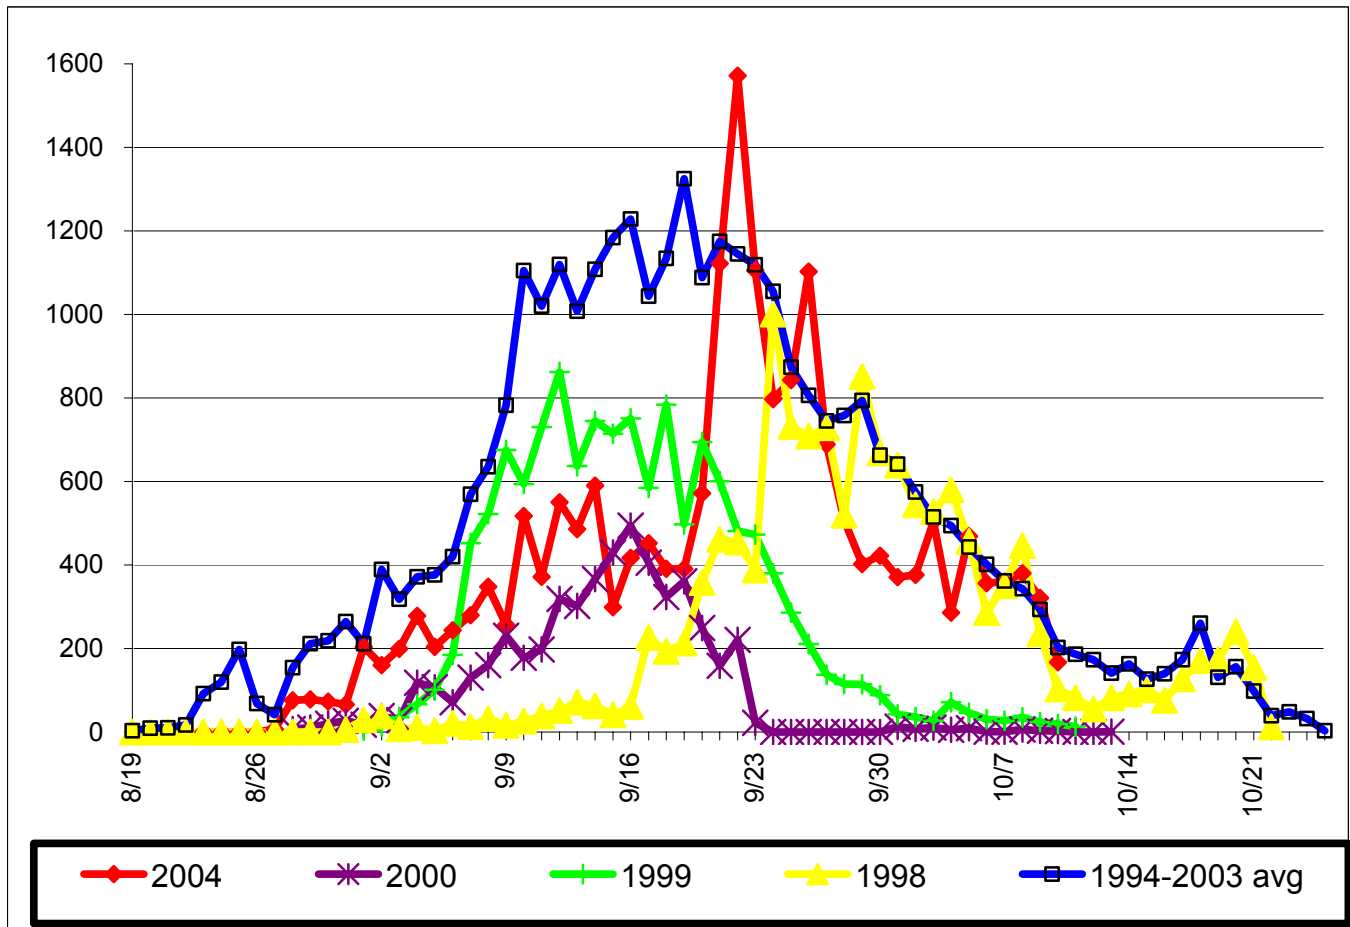

Figure 4. Comparative chum salmon counts at the Fishing Branch weir—note early finish in 2004 (data provided by Fisheries and Oceans Canada 2004).

The two additional population estimates were made utilising the tag recovery results from the Fishing Branch weir in combination with the mark-recapture data. One accounts for the number of chum tagged in the mark-recapture program up until the last tag number recovered at the Fishing Branch weir (1,140) and the number of chum that passed through the weir only during the mark-recapture program (17,795). This results in a population estimate of 30,125 (+/- 1,430 at 95% confidence level). A second estimate accounts for the total number of chum tagged in the mark-recapture program (1,276) and the total number of chum that passed through the weir. This results in a population estimate of 37,257 (+/- 1,903 at 95% confidence level), with the assumption that an equal proportion of chum (59%) returned to the Fishing Branch River during the mark-recapture program as prior to the start of the mark/recapture program. See Figure 3 for further information.

At the time when the tagging/test fisheries as well as the Fishing Branch weir operations were suspended, chum salmon were still being caught, albeit in decreasing numbers. Due to this, it should be assumed that the entire migrating population of chum was not sampled and therefore the actual population of migrating chum was higher than the estimates identified above. While it is not possible to estimate the significance of such additional numbers of chum, it can be assumed that the vast majority of the run was sampled (See Figure 4).

These additional estimates indicate that the mark-recapture population estimate was in fact high. However, they also indicate that the actual population was within the lower range of the confidence interval generated for the mark-recapture program.

The high population estimate and the large confidence interval from the mark-recapture program can be attributed to two problems with the data collected. One is the difference between the number of chum tagged and the number of chum caught in the test fishery. The other is the low number of tags recovered in the test fishery. The latter would figure more prominently in the total population estimate, as the total numbers of chum tagged and those captured in the test fishery were both high, and differed by less than 10%. Further to this, the weekly population estimates were obviously based on smaller sample sizes, with proportionally much greater differences between the mark and recapture samples. Therefore, the weekly estimates were plagued with uncertainty resulting from both differences in sample sizes, as well as low numbers of tag recoveries.

4.2 Observation of Spawning Chum Salmon at David Lord Creek

On September 21st and September 22nd, the tagging fishery was not conducted due to logistical constraints. Due to the lack of tagging on these dates, the test fishery was re-located for September 23rd, and was conducted 38 km upstream from Old Crow at the mouth of David Lord Creek. It was at this location that the field crew observed a concentration of chum salmon that appeared to be spawning. Three salmon at the location were observed to have orange spaghetti tags attached, consistent with the tags applied by our project. A number of spawning redds were observed with chum salmon on them, and, a small number of deceased chum salmon were also observed in the area. The spawning site was located in the Porcupine River at the confluence of David Lord Creek, where a large alluvial fan is formed. A number of salmon were caught in the test fishery at this location, and these results are summarized in Table 3. The complete data set for chum salmon sampled at this location is included in Appendix 2. Among the fish captured at this location were two that were marked with tags applied in the mark-recapture program. One of the tags (T000641) was applied on September 4th, 2004, and the fish was recaptured in a spawned out state. The second tag captured here (T001367) was applied on Sep 20th, 2004 and the fish was in good condition, therefore indicating that it may have been in migration through the site.

4.3 Travel Time of Tagged Chum Salmon

The travel time of chum salmon between the tagging and test fishery was found to be faster than the travel time between the tagging site and the Fishing Branch weir by a difference of 1.2 km/day. While the difference is very slight, it may be attributed to the stresses placed upon the fish in the tagging process (Milligan pers. comm. 2004). The travel time between the tagging site and the Fishing Branch weir in this year's mark-recapture program differed from the average travel time in 2003 by only 0.4 km/day (Anderton, 2003). This indicates that the chum salmon of the Porcupine River travel at a reasonably constant rate from year to year. Information from future chum mark-recapture programs will assist in confirming this observation. All detailed data for individual tag recoveries from the test fishery and at the Fishing Branch weir can be found in Appendices 1 and 2.

4.4 Spawning Destination of Porcupine River Chum Salmon

During the 2003 mark – recapture program, 88% of all tags applied were counted through the Fishing Branch Weir (Anderton 2003). With only 59% of tags applied having been accounted for at the weir in 2004, it can be assumed that a significant portion of the chum run spawned in locations other than upstream of the weir on the Fishing Branch River. Even if we allow for a liberal possible mortality of 10% of tagged chum salmon, at least 31% of the run may have spawned in other locations in 2004. A number of possible reasons for the difference in the proportion of tags counted through the Fishing Branch weir during 2003 and 2004 are listed below.

- The sample size in 2003 was too small (only 319 chum were tagged) (Anderton, 2003), and therefore was not entirely representative.
- Variation in spawning locations used between years.
- Unusually low water levels in 2004 affected migrating/spawning behaviour.

The small sample obtained in 2003 was likely not representative of the whole population, due to both its size and the fact that the sampling was not distributed evenly throughout the run. This was not the case in 2004, as significant sample sizes were obtained, and sampling was conducted reasonably distributed over the entire duration of the run. It is possible that some variation in spawning destinations does occur from year to year as well. Further, extreme low water conditions in 2004 may have influenced migration/spawning behaviour. The observation and capture of spawning chum at the mouth of David Lord Creek may be an indication of both possibilities. Chum salmon were also observed by community members to be spawning in similar habitat at the mouth of the Bluefish River (downstream from the tagging site) in 2004 (Josie pers. comm. 2004). Spawning chum salmon have never been observed in these locations before, and both are in areas frequented by community members. Dynamic or sudden changes in spawning behaviour may be a response to environmental changes (such as a sudden change in water availability/levels) and may be an inherent survival strategy involving regular attempts at colonization of available habitats (Levin & Schiwe 2002).

5.0 CONCLUSION

This project used the knowledge and experience obtained during the 2003 mark-recapture program to increase the sampling efficiency which resulted in a much more significant number of fish being tagged, and subsequently recaptured in the test fishery. It was possible to generate weekly estimates of the number of chum salmon, however such estimates contained a large margin of error. As well, these estimates and the total population estimate can be considered to be high. However, such data and associated statistics provide important information that will assist in the design and management of future mark-recapture efforts on the Porcupine River. As well, tag recovery at the Fishing Branch weir provided valuable information regarding the spawning destination of Porcupine chum stocks and the significance of the Fishing Branch River as a major spawning destination. Similar data in this regard will be required from future chum tagging efforts to determine if 2004 results are typical, if annual variations occur, and/or if 2004 is an anomaly in terms of the percentage of chum migrating to the Fishing Branch River. This project can be considered a success upon which a valuable, long-term mark-recapture

program can be developed. Each year that such efforts are undertaken will improve both the sampling methodology and the relevance of the data obtained.

6.0 RECOMMENDATIONS

It is recommended that the knowledge and experience gained during this project be used to further refine the methodology of future chum salmon mark-recapture programs on the Porcupine River. Developing a successful mark-recapture program that functions as an “in-season” measure of run strength is a long-term process. Each year, the methodology is further developed and the contextual understanding of the data is improved. It is recommended that such efforts be continued into the future. The results of this project provide an excellent base from which to both improve the accuracy of predictions, and reduce the margin of error. The following suggestions may facilitate improvement of the mark-recapture program.

- Capture more fish in the test fishery. The capture of more fish (and thus tags) this will increase the accuracy of the run estimate and reduce the margin of error.
- Increase the distance between the tagging and test fisheries to ensure adequate mixing of tagged fish into the overall population (this may increase the rate of tag recovery).
- Explore other appropriate options to increase the rate of tag recovery.
- Tag chum captured in the test fishery with a different coloured spaghetti tag. This will assist in better estimating overall run strength, as well as providing a much larger sample from which to assess the proportion of chum spawning upstream of the Fishing Branch enumeration weir.

7.0 ACKNOWLEDGEMENTS

Funding for this project was provided by the Yukon River Salmon Restoration and Enhancement Fund. Pat Milligan and Rick Ferguson (Fisheries and Oceans Canada) provided technical support; William Josie (Vuntut Gwitchin First Nation – Natural Resources) provided general project direction and assistance with logistics. Field crewmembers Harold Frost Jr., Stan Njootli Jr., and William Smith provided the effort and practical input to ensure the project’s success.
